Program Slicing

DAVID W. BINKLEY AND KEITH BRIAN GALLAGHER

Baltimore, Maryland

A hundred times every day, I remind myself that my inner and outer life depends on the labors of other men, living and dead, and that I must exert myself in order to give in the measure as I have received and am still receiving.

A. Einstein

Abstract

Program slicing is a technique for reducing the amount of information that needs to be absorbed by a programmer. Given a point of "interest" in a program, described by a variable and a statement, a program slice gives all the statements that contributed to the value of the variable at the point, and elides unnecessary statements. This chapter surveys techniques for computing program slices and the applications of program slicing to development, testing, maintenance, and metrics.

1. Introduction

At the fifteenth International Conference on Software Engineering (ICSE) in 1993, Mark Weiser received recognition for the best paper at the fifth ICSE. Weiser reported that "Program Slicing" [90], the conference paper, and its journal incarnation of the same name [93], were cited about 10 times a year from 1984 to 1989 and about 20 times a year in 1990 and 1991. Our search of the "Science Citation Index" found 9 citations in 1992; 9 citations in 1993; and 15 citations in 1994, and included universities in 10 countries and 8 industrial laboratories. This is a lower bound as our bibliography has only 7 items that do not cite [93]. Since so many researchers and practitioners have been citing this seminal work, herein we attempt to collate, summarize, and organize the results that have followed.

Program slicing is a decomposition technique that extracts from a program statements relevant to a particular computation. Informally, a slice provides the answer to the question "What program statements potentially affect the computation of variable v at statement s?" An observer viewing the execution of a program and its slice cannot determine which is which when attention is focused on statement s. It is as if the observer has a window through which only part of the program state can be seen as illustrated by the "clear window" in Fig. 1.

The utility and power of program slicing comes from the ability to assist in tedious and error-prone tasks such as program debugging [1, 46, 50, 60–62, 84, 91], testing [3, 11, 15, 18, 27, 47, 50, 53, 83], parallelization [21, 92], integration [78, 39, 76, 77, 79], software safety [29], understanding [22, 52, 65, 71], software maintenance [28, 54, 66, 70, 73, 74], and software metrics [58, 59, 68, 67]. Slicing does this by extracting an algorithm whose

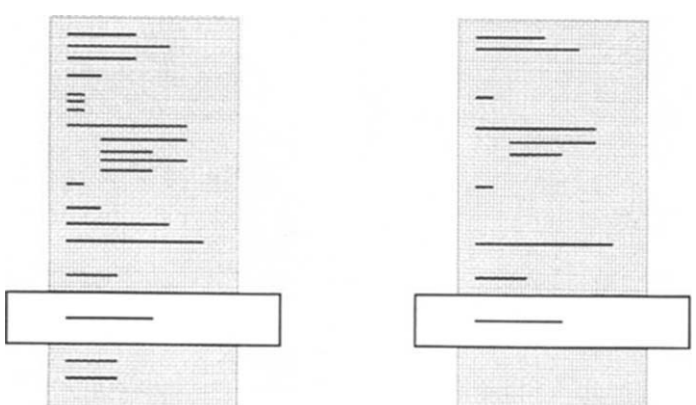

FIG. 1. The programmer's view of a slice.

computation may be scattered throughout a program from intervening irrelevant statements. Consequently, it should be easier for a programmer interested in a subset of the program's behavior to understand the slice.

1.1 A Brief History

This section provides a brief history of program slicing and introduces the principal terminology. A slice is taken with respect to a *slicing criterion* $<s, v>$, which specifies a location (statement s) and a variable (v). This can be easily extended to slicing with respect to a collection of locations and a collection of variables at each location by taking the union of the individual slices. However, to simplify the exposition, we present definitions for the single statement and single variable case.

Program slices, as originally introduced by Weiser [89, 90, 93], are now called *executable backward static* slices. *Executable* because the slice is required to be an executable program. *Backward* because of the direction edges are traversed when the slice is computed using a *dependence graph.* Finally, *static* because they are computed as the solution to a static analysis problem (i.e., without considering the program's input).

Weiser's requirement that a slice be executable provided an empirical validation of the concept. Although this seems reasonable, many applications of program slicing (e.g., debugging) do not require executable slices. This issue is considered in Section 2.

Weiser originally used a control-flow graph as an intermediate representation for his slicing algorithm. Ottenstein *et al.* [24, 69] later noted that backward slices could be efficiently computed using the program dependence graph as an intermediate representation by traversing the dependence edges backwards (from target to source). This observation was pursued vigorously and rigorously by Horwitz *et al.* [36–40, 42–44, 78, 79, 82], who introduced the notion of *forward* slicing in [44]. Informally, a forward slice answers the question "What statements are affected by the value of variable v at statement s?"

Finally, Korel and Laski introduced the notion of *dynamic* slicing [49, 51]: a slice computed for a particular fixed input. The availability of runtime information makes dynamic slices smaller than static slices, but limits their applicability to that particular input. As with Weiser's algorithm, Korel and Laski's algorithm uses a control-flow graph as an intermediate representation. Agrawal and Horgan later presented a dynamic slicing algorithm that used the program dependence graph as an intermediate representation [5, 6].

This chapter is organized into three major sections. Section 2 discusses static slicing as a data-flow problem and as a graph-reachability problem; then we discuss dynamic slicing as a data-flow problem and as a graph-reachability

problem; and closes with a collection of alternative methods for computing slices. The third section looks at applications of the idea of program slicing, without regard to any particular method of computing the slice.

2. Computing Slices

The following terminology is used in this section to discuss the computation of slices.

Definition 1: Graph. A directed graph G is a set of nodes N and a set of edges $E \subseteq N \times N$. For edge $(n, m) \in E$, m is an *immediate successor* of n and n is an *immediate predecessor* of n. G contains two special nodes, $n_{initial}$, which has no predecessors, and n_{final}, which has no successors. Furthermore, there is a path from $n_{initial}$ to every node in G and a path from n_{final} to every node in G^{-1}, the inverse graph of G. ■

Definition 2: Control-Flow Graph. A control-flow graph for program P is a graph in which each node is associated with a statement from P and the edges represent the flow of control in P. Let V be the set of variables in P. With each node n (i.e., each statement in the program and node in the graph) associate two sets: $REF\ (n)$, the set of variables whose values are referenced at n, and $DEF\ (n)$, the set of variables whose values are defined at n. ■

Definition 3: Program Slice. For statement s and variable v, the slice of program P with respect to the slicing criterion $<s,v>$ includes only those statements of P needed to *capture* the behavior of v at s. ■

Exactly what is meant by "capture" varies. The most intuitive definition is presented in the definition of an *executable slice.* Other definitions are examined later in this section.

Definition 4: Executable Program Slice. For statement s and variable v, the slice S of program P with respect to the slicing criterion $<s, v>$ is any executable program with the following properties:

1. S can be obtained by deleting zero or more statements from P.
2. If P halts on input I, then the value of v at statement n each time n is executed in P is the same in P and S. If P fails to terminate normally[1] n may execute more times in S than in P, but P and S compute the same values each time n is executed by P. ■

[1] A program fails to terminate normally if it diverges or terminates abnormally, for example, with a division by zero error.

Note that every program has itself as a slice on any criterion.

Example. The program of Fig. 2 never executes Statement 5, while the slice on <5, *c*> includes only Statement 5, which is executed once. ■

2.1 Slicing Control-Flow Graphs

This section describes computing a slice as the solution to a data-flow problem using a control-flow graph as an intermediate representation. It considers a progression of harder slicing problems beginning with slicing straight-line programs, then considering structured control flow, unstructured control flow, data structures, and, finally, procedures.

Computing a slice from a control-flow graph is a two-step process: First requisite data-flow information is computed and then this information is used to extract the slice. The data-flow information is the set of *relevant* variables at each node *n*. For the slice with respect to <*s*, *v*>, the relevant set for each node contains the variables whose values (transitively) affect the computation of *v* at *s*. The second step identifies the statements of the slice. These include all nodes (statements) *n* that assign to a variable relevant at *n* and the slice taken with respect to any predicate node that directly controls *n*'s execution.

2.1.1 *Slicing Flow Graphs of Straight-Line Programs*

Straight-line code contains only assignment statements executed one after the other. For such code the additional slices with respect to predicate nodes are not required. We begin by assuming that expression evaluation does not alter the values of its operands. *Relevant sets* for the slice taken with respect to <*n*, *v*> are computed as follows [60]:

1. Initialize all relevant sets to the empty set.
2. Insert *v* into *relevant*(*n*).

n	statement
1	c = 0
2	while (TRUE)
3	c = 1
4	endwhile
5	c = 2

n	statement
5	c = 2

FIG. 2. "Sliceable" divergent program and the convergent slice taken with respect to <5, *c*>.

3. For m, n's immediate predecessor, assign $relevant(m)$ the value $(relevant(n) - DEF(m)) \cup (REF(m)$ if $relevant(n) \cap DEF(m) \neq \emptyset)$.
4. Working backwards, repeat step 3 for m's immediate predecessors until $n_{initial}$ is reached.

Example. Figure 3 shows the relevant sets for a slice taken with respect to <8, a>. The relevant sets are computed from line 8 to line 1. For example, $relevant(7) = (relevant(8) - DEF(7)) \cup (REF(7)$ if $relevant(8) \cap DEF(7) \neq \emptyset) = (\{a\} - \{a\}) \cup (\{b, c\}$ if $\{a\} \cap \{a\} \neq \emptyset) = \{b, c\}$, and $relevant(2) = (\{b, c\} - \{c\}) \cup (\emptyset$ if $\{b, c\} \cap \{c\} \neq \emptyset) = \{b\}$. If we were interested in some variable other than a, the computation of the relevant sets would be different; thus, different relevant sets must be computed for different slices. ■

The relevant sets may be viewed as a flow of sets of variables; the slice is the set of statements that disturb this flow. If no relevant variables are *defined* at a statement, then the relevant set flows through unperturbed. On the other hand, if a relevant variable is *defined*, then the statement is added to the slice. In Fig. 3, for example, the slice with respect to <8, a> includes lines 7, 6, 2, and 1 (line 6 changes the b that is in the relevant set). Note that, in practice, the relevant sets and the statements in the slice are computed in a single pass.

2.1.2 Slicing Structured Programs

In straight-line programs each statement has a single unique predecessor. In the presence of structured control flow, a statement may have multiple control predecessors. The preceeding algorithm requires three modifications to handle this: first, the inclusion of control sets; second, a rule for combining relevant sets at control join points; and, finally, iteration of the relevant set computation.

n	statement	$refs(n)$	$defs(n)$	$relevant(n)$
1	$b = 1$		b	
2	$c = 2$		c	b
3	$d = 3$		d	b, c
4	$a = d$	d	a	b, c
5	$d = b + d$	b, d	d	b, c
6	$b = b + 1$	b	b	b, c
7	$a = b + c$	b, c	a	b, c
8	*print* a	a		a

FIG. 3. Relevant sets for <8, a>.

n	statement	$refs(n)$	$defs(n)$	$control(n)$
1	$b = 1$		b	
2	$c = 2$		c	
3	$d = 3$		d	
4	$a = d$	d	a	
5	*if* (a) *then*	a		
6	$d = b + d$	b, d	d	5
7	$c = b + d$	b, d	c	5
8	*else*			5
9	$b = b + 1$	b	b	8
10	$d = b + 1$	b	d	8
11	*endif*			
12	$a = b + c$	b, c	a	
13	*print* a	a		

FIG. 4. Control sets.

The control set *control*(n) associates with node (statement) n, the set of predicate statements that directly controls n's execution [60]. The use of a set here facilitates the transition to unstructured control flow in Section 2.1.3. For a structured program, *control*(n) contains a single entry, the loop or conditional statement that controls the execution of n, or is emply, when n is a *top-level* statement. For example, in Fig. 4 *control*(6) includes statement 5, the *if* (a) *then;* the control sets for statement 9 includes statement 8, the *else,* whose control set also includes statement 5. Whenever a statement is added to the slice, the members of its control set, k, are added to the slice along with statements in the slice taken with respect to $<k, REF(k)>$.

At join points (where two nodes have the same predecessor), the relevant set is the union of the relevant sets of the two nodes. For example, in Fig. 5, *relevant*(5) is the union of *relevant*(6) and *relevant*(9). This assumes that

n	$refs(n)$	$refs(n)$	$control(n)$	$relevant(n)$
1		b		a
2		c		a, b
3		d		a, b
4	d	a		a, b
5	a			b, c, d
6	b, d	d	5	b, d
7	b, d	c	5	b, c
8			5	c, d
9	b	b	8	c, d
10	b	d	8	c, d
11				b, c
12	b, c	a		b, c
13	a			a

FIG. 5. Relevant sets on a at 13.

the expression in the conditional at the join point has no side effects. If it does, then after the union, step 3 of the relevant set computation must be performed to update the set to account for the side effects of the expression.

Example. Figure 5 shows the data necessary to calculate the slice with respect to <13, *a*> of the program shown in Fig. 4. The slice is normally computed in conjuction with the relevant sets: Working backward from line 13, since *DEF*(12) ∩ *Relevant*(13) ≠ ∅, line 12 is included in the slice and its relevant set is assigned {*b, c*}. No change occurs at line 11. Line 10 in included in the slice because *DEF*(10) ∩ *Relevant*(11) ≠ ∅; *relevant*(10) is assigned {*c, d*}. Next, lines 5 and 8 are included in the slice because *control*(10) includes 8 and *control*(8) includes line 5. Along with these lines, the lines in the slices with respect to <8, *REF*(8)> = <8,∅> and <5, *REF*(5)> = <5, *a*> are also included. These add to the slice lines 4 and 3. Finally, line 6 completes the slice. ■

The third change is required to handle loops. The absence of loops allows a slice to be computed in a single pass over the control-flow graph; the presence of loops requires iteration over parts of the graph, in particular, iteration over each loop until the relevant sets and slice stabilize. Hausler [35] has shown that the maximum number of iterations is the same as the number of assignment statements in the loop. Figure 6 shows how the upper bound is reached.

2.1.3 Slicing Unstructured Programs

The addition of *goto* statesments, and its restricted forms such as *return, exit, break,* and *continue,* complicates the construction of the control sets. One solution is to restructure the program as *goto*-less [56] and then slice. The drawback to this method is that the structured version may be significantly textually dissimilar from the original.

Lyle [60] proposed a simple and conservative solution to slicing over unstructured control flows: if a *goto* statement has a nonempty relevant

n	statement
0	*while* (*a*)
1	$x_n = x_{n-1}$
2	$x_{n-1} = x_{n-2}$
	...
n	$x_2 = x_1$
n + 1	*endwhile*

FIG. 6. A *while* statement that needs *n* passes to compute a slice when x_1 is in the criteria.

set, include it in the slice. The targets of the *goto* are included, and so on until the slice stabilizes.

An alternative approach [26] is to note that *goto* statements are associated with *labels*. Rather than look for *goto* statements to include in the slice, look for labeled statements that are included in the slice. Then include only the *goto* statements that branch to these labels. This algorithm was devised for a language in which the only labels are targets of *goto*'s, a labeled statement does no computation, and does not have explicit compound statements. That is, statements of the form

```
if ( b ) then {
    /* compute X */
} else {
 /* compute Y */
}
```

are replaced by the semantically equivalent:

```
if ( b )  goto L1
      /* compute Y */
goto L2
L1:
      /* compute X */
L2:
```

Each statement of the form

```
label :  statement ;
```

is transformed to the semantically equivalent

```
label :  null ;
statement ;
```

Definition 5: Labeled Block. A *labeled block* is a basic block[2] that begins with a labeled statement and ends when one of the following occurs.

[2] A *basic block* [48] is a sequence of consecutive instructions that are always executed from start to finish.

1. The basic block ends.
2. Another labeled block begins; that is, another labeled statement occurs. ■

Definition 6: Pseudo-Label. Let L be the label of the statement that begins a labeled block B. The remaining statements in B are said to have pseudo-label L. ■

On the pass after a pseudo-labeled statement is added to the slice, as each *goto* statement is examined it is placed in the slice according to whether or not its target (pseudo-)label has already been added to the slice. The noncomputing labeled statements are added if the actual label matches a pseudo-label in the slice.

2.1.4 Arrays, Records, and Pointers

The handling of composite structures and pointers requires a change to the $DEF(n)$ and $REF(n)$ sets. A simple approach for arrays is to treat each array assignment as both an assignment and a use of the array. For

$$\text{n: } a[i] := x;$$

one may naively assume that $DEF(n) = \{a\}$ and $REF(n) = \{i, x\}$. But the new value of a also depends on the old value of a, so a must also be included. The correct value for $REF(n)$ is $\{a, i, x\}$. However, this approach leads to correct, but unnecessarily large slices.

To more precisely determine if there is a dependence between a statement that contains an assignment to $a[f(i)]$ and a statement that contains a use of $a[g(j)]$, we must answer the question "Can $f(i) = g(j)$?" In general, this question is unanswerable, although it can be solved for some common index expression types. These solutions are often *one sided:* Algorithms exist to determine if the answer to the question is "no." Otherwise, no information is obtained. To illustrate this, consider the greatest common divisor (GCD) test applied to the following loop:

```
i = 0
while (i < N)
{
    X[a1 * i + a0 ] = ...
    ...= X[b1 * i + b0 ]
    i = i + 1
}
```

If $gcd(a_1, b_1)$ does not divide $(b_0 - a_0)$ then the GCD test demonstrates the absence of a dependence between s_1 and s_2, but if $gcd(a_1, b_1)$ divides

($b_0 - a_0$), the solution may lay outside the range 0. . . N. Other tests [64, 72] are similarly one sided. If none of these tests can prove the absence of a flow dependence, then one is assumed to exist. This provides a more precise, yet safe, approximation to the correct data relationships. Once this has been done, the slicing algorithm proceeds as in the absence of arrays.

Records are simple, if not tedious, to treat in a slicing algorithm. Unlike arrays, each field of a record is identified by a constant (the field's name). This allows occurrences of *record.field* to be treated as occurrences of the simple variable *record_field*. The assignment of one record to another is modeled as a sequence of field assignments.

The multiple levels of indirection for both assignment and reference of pointers create difficult problems. One must obtain every possible location to which a pointer could point. If a variable is *def*ined or *ref*erenced through a chain of pointers (e.g., *****a), then all intermediate locations in the accessing of the variable must be considered as *ref*ed locations.

Lyle *et al.* [63] construct and then prune a *pointer state graph* (PSS) for expression $*^k a$. The $PSS_k(a)$ is a directed graph with single source a and is defined recursively as

$$PSS_k(a) = \begin{cases} a, & \text{if } k = 0 \\ \{v \mid * a = v\}, & \text{if } k = 1 \quad \& \; edge(a, v) \in PSS_k(a) \\ \{v \mid v \in PSS_1(u) \wedge u \in PSS_{i-1}(a)\}, & \text{otherwise } \& \; edge(u, v) \in PSS_k(a). \end{cases}$$

$PSS_k(a)$ gives the possible references of $*^k a$. It is then pruned: $R_{PSS_k(a)}(w) = \{v \in \mathrm{PSS}_k(a) \wedge dist(v, w) \leq k\}$, where $dist(w,v)$ is the distance, measured in edges, between v and w. $R_{PSS_k(a)}(w)$ is used to compute $DEF(n)$ by eliminating the indirect definitions of w that cannot be reached via k levels of indirection from a. See [63] for a detailed discussion.

2.1.5 Interprocedural Slicing

Slicing across procedures[3] complicates the situation due to the necessity of translating and passing the criteria into and out of calling and called procedures. When procedure P calls procedure Q at statement i, the active criteria must first be translated into the context of Q and then recovered once Q has been sliced.

To translate a set of criteria, C, into a called procedure, for each $v \in relevant(succ(Q)) \cap actual\_parameter(Q)$ map $v \rightarrow \omega$, the corresponding formal parameter of Q. Then generate new criteria $<n^Q_{final}, \omega>$. If $v \in relevant(succ(Q)) \cap local\_definition(Q)$, that is, a local redefinition of v

[3] This section follows closely that of Weiser [93].

occurs, change the line number of criteria involving v to i, the call-site of Q. When $n^Q_{initial}$ is reached, unmap $\omega \rightarrow v$, and replace $n^Q_{initial}$ with i. Weiser called this new set of criteria $DOWN_0(C)$.

This is essentially an in-line replacement of each procedure occurrence, with appropriate substitutions. Globals pass into the called procedure undisturbed if their visibility is not blocked by a variable in Q; thus references to them inside the procedures are captured correctly. This method was introduced early in the development of the idea of slicing and does not address hard questions about pointers, aliasing, function parameters, etc.

When P is called from statement j of Q, criteria must be generated to slice up into Q. The new criteria are generated in similar fashion to the calling context. Criteria involving local variables are discarded, so that no undefined references are passed. Criteria involving formal parameters are mapped into the corresponding actual of Q with new line number j. Weiser called this set $UP_0(C)$.

The sets $Down_0(C)$ and $UP_0(C)$ are then mapped to functions from criterion to criterion: $Down(CC) = \cup_{C \in CC} DOWN_0(C)$ and $UP(CC) = \cup_{C \in CC} UP_0(C)$. Union and transitive closure are defined in the usual way for these relations. Thus $(DOWN \cup UP)^*(C)$ will give a complete set of criteria to obtain the interprocedural slice for any criteria. This conservative, but correct, approximation was improved by [44].

2.2 Slicing as a Graph-Reachability Problem

Ottenstein and Ottenstein [69] observed that the program dependence graph (PDG), used in vectorizing and parallelizing compilers and program development environments, would be an ideal representation for constructing program slices: "Explicit data and control dependence make the PDG ideal for constructing program slices" [69].

This section first discusses a variation of the PDG used to compute intraprocedural slices of structured programs and the extensions necessary to slice programs that contain procedures and procedure calls [39]. Both of these algorithms have three steps:

1. Construct a dependence graph from the program.
2. Slice the dependence graph.
3. Obtain a sliced program from the sliced graph.

The advantage of the dependence graph approach is that steps 2 and 3 are efficient. For example, step 2 is linear in the size of the graph. However, step 1, the construction of the PDG is, $O(n^2)$ in the number of statements in the program. To focus on the slicing algorithms, this section does not

discuss how step 1, dependence graph construction, is accomplished (see [24, 34, 39, 44, 57, 69] for details).

2.2.1 Intraprocedure Slicing

The PDG used for intraprocedural slicing by Horwitz *et al.* [39] is a modified version of the dependence graph considered by Ottenstein and Ottenstein [69]. The PDG for program P, denoted by G_P, is a directed graph whose vertices are connected by several kinds of edges. The vertices of G_P represent the assignment statements and control predicates that occur in program P. In addition, G_P includes a distinquished vertex called the *entry vertex.*

G_P is a multigraph. Not only can it have more than one edge between two vertices, it can have more than one edge of a given kind between two vertices. Edges in G_P represent *dependences* among program components. An edge represents either a *control dependence* or a *flow dependence.* Control dependence edges are labeled **true** or **false,** and the source of a control dependence edge is always the entry vertex or a predicate vertex. A control dependence edge from vertex u to vertex v, denoted by $u \rightarrow_c v$, means that during execution, whenever the predicate represented by u is evaluated and its value matches the label on the edge to v, then the program component represented by v will eventually be executed if the program terminates. For structured languages, control dependences reflect the program's nesting structure. Consequently, PDG G_P contains a *control dependence edge* from vertex u to vertex v of G_P iff one of the following holds:

1. u is the entry vertex, and v represents a component of P that is not nested within any loop or conditional; these edges are labeled **true.**
2. u represents a control predicate, and v represents a component of P immediately nested within the loop or conditional whose predicate is represented by u.

If u is the predicate of a *while* loop, the edge $u \rightarrow_c v$ is labeled **true;** if u is the predicate of a conditional statement, the edge $u \rightarrow_c v$ is labeled **true** or false according to whether v occurs in the **then** branch or the **else** branch, respectively.

A flow dependence edge from vertex u to vertex v means that the program's computation might be changed if the relative order of the components represented by u and v were reversed. The flow dependence edges of a PDG are computed using data-flow analysis. A PDG contains a flow

dependence edge from vertex u to vertex v, denoted by $u \rightarrow_f v$, iff all of the following hold:

1. u is a vertex that defines variable x.
2. v is a vertex that uses x.
3. Control can reach v after u via an execution path along which there is no intervening definition of x.

Flow dependences can be further classified as *loop carried* or *loop independent.* A flow dependence $u \rightarrow_f v$ is carried by loop L, denoted by $u \rightarrow_{lc(L)} v$, if in addition to items 1, 2, and 3 given, the following also hold:

4. There is an execution path that both satisfies the conditions of item 3 above and includes a back edge to the predicate of loop L.
5. Both u and v are enclosed in loop L.

A flow dependence $u \rightarrow_f v$ is loop independent, denoted by $u \rightarrow_{li} v$, if in addition to items 1, 2, and 3 there is an execution path that satisfies item 3 above and includes *no* back edge to the predicate of a loop that encloses both u and v. It is possible to have both $u \rightarrow_{lc(L)} v$, and $u \rightarrow_{li} v$.

When there is more than one loop-carried flow dependence edge between two vertices, each is labeled by a different loop that carries the dependence. Figure 7 shows an example program and its PDG.

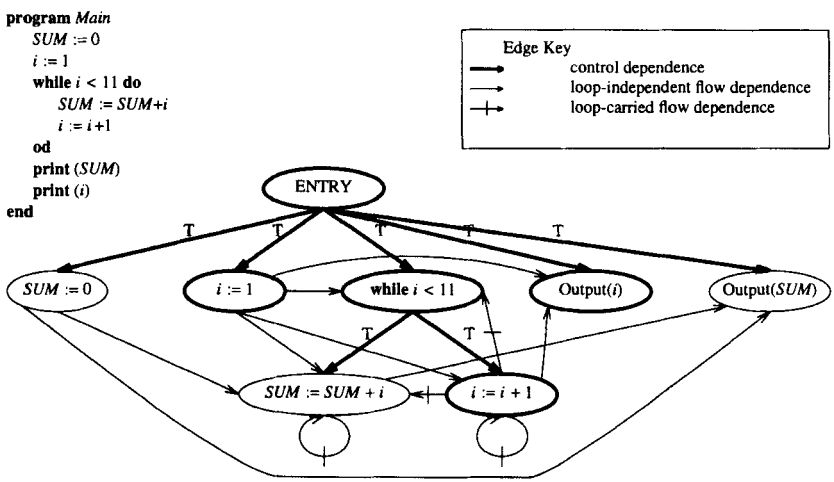

FIG. 7. An example program, which sums the integers from 1 to 10 and leaves the result in the variable *sum*, and its program dependence graph. The vertices of the slice of this PDG taken with respect to the final use of i are shown in bold.

For vertex s of PDG G, the *slice* of G with respect to s, denoted by *Slice*(G, s), is a graph containing all vertices on which s has a transitive flow or control dependence (i.e., all vertices that can reach s via flow and/or control edges):

$$V(Slice(G, s)) = \{v \in V(G) \mid v \rightarrow^*_{c,f} s\}.$$

The edges of *Slice*(G, s) are those in the subgraph of G induced by V (*Slice*(G, s)):

$$E(Slice(G, S)) = \{v \rightarrow_f u \in E(G) \mid v, u \in V(Slice(G, S))\} \cup \{v \rightarrow_c u \in E(G) \mid v, u \in V(Slice(G, S))\}$$

The vertices of the slice of the PDG shown in Fig. 7 taken with respect to the output vertex for i are highlighted in Fig. 7.

Slicing programs with composite data structures involves changing the computation of the flow dependence edge only. Two methods for slicing in the presence of arbitrary control flow (programs containing *goto*'s) require modification of the control dependence subgraph of the PDG, but not the slicing algorithm. Choi and Ferrante [20] augment the control-flow graph that is used in the construction of the PDG with a set of *fall-through* edges, that is, the lexcial successor of the *goto* in the source text. The fall-through edges capture the requisite control flow when a *goto* statement is deleted from the slice.

Ball and Horwitz [7] describe a similar technique in which jump statements are represented by pseudo-predicate vertices, which always evaluate to **true.** The outgoing control edge labeled **true** is connected to the target of the jump, while a **false** successor is connected to the jump statement's continuation; that is, the statement that would be executed if the jump were a no-op.

Harrold *et al.* [34] describe an efficient construction of PDG's that captures exact control dependence (i.e., *goto*'s) but uses neither a control-flow graph or a postdominator tree as an auxiliary structure. This construction technique improves the methods of [7, 20] for construction of the PDG. During the parse, a *partial control dependence subgraph,* which incorporates exact control, is constructed. The partial control dependence subgraph manages control flow by ordering the nodes implicitly during construction or explicitly by the creation of control edges. The presence of *goto*'s does require a minor change to step 3 of the slicing algorithm (the projection of a program from the sliced PDG). This change ensures that labels of statements not in the slice are included in the resulting program if a *goto* to that label is in the slice.

Another method for computing slices in the presence of arbitrary control flow avoids changing the PDG at the expense of modifying the slicing

algorithm use in step 2 [2]. This method maintains two relations postdominator and lexical-successor. The algorithm computes a slice from the graph used by HPR algorithm using step 2 and then looks for a *jump* statement not in the slice whose nearest postdominator in the slice is different from the nearest lexical successor in the slice. Such statements are then added to the slice. As with the algorithms in [7, 20, 34], step 3 must be modified to include any necessary labels.

2.2.2 Interprocedural Slicing of Dependence Graphs

Interprocedural slicing as a graph-reachability problem requires extending of the PDG and, unlike the addition of data types or unstructured control flow, it also requires modification of the slicing algorithm. The PDG modifications represent call statements, procedure entry, parameters, and parameter passing. The algorithm change is necessary to account correctly for procedure calling context. This section describes the interprocedural slicing algorithm presented in [44], which is based on an extension of the PDG called the *system dependence graph* (SDG).[4] Horwitz *et al.* [44] introduced the term *system dependence graph* for the dependence graphs that represents multiprocedure programs. The term *system* will be used to emphasize a program with multiple procedures.

The SDG models a language with the following properties:

1. A complete *system* consists of a single main procedure and a collection of auxiliary procedures.
2. Parameters are passed by value-result.

Techniques for handling parameters passed by reference and for dealing with aliasing are discussed at the end of this section.

Horwitz *et al.* [44] make the further assumption that there are no call sites of the form $P(x, x)$ or $P(g)$, where g is a global variable. The former restriction sidesteps potential copy-back conflicts. The latter restriction permits global variables to be treated as additional parameters to each procedure; thus, they are not discussed explicitly.

An SDG is made up of a collection of procedure dependence graphs connected by interprocedural control- and flow-dependence edges. Procedure dependence graphs are similar to program dependence graphs except that they include vertices and edges representing call statements, parameter

[4] The term "SDG" is used because the term "PDG" is associated with graphs that represent single procedure programs.

passing, and transitive flow dependences due to calls (we will use the abbreviation "PDG" for both procedure dependence graphs and program dependence graphs). A call statement is represented using a *call* vertex; parameter passing is represented using four kinds of *parameter* vertices: On the calling side, parameter passing is represented by *actual-in* and *actual-out* vertices, which are control dependent on the call vertex; in the called procedure, parameter passing is represented by *formal-in* and *formal-out* vertices, which are control dependent on the procedure's entry vertex. Actual-in and formal-in vertices are included for every global variable that may be used or modified as a result of the call and for every parameter; formal-out and actual-out vertices are included only for global variables and parameters that may be modified as a result of the call. Interprocedural data-flow analysis is used to determine the parameter vertices included for each procedure [8, 10].

Transitive dependence edges, called *summary* edges, are added from actual-in vertices to actual-out vertices to represent transitive flow dependences due to called procedures. These edges were originally computed using a variation on the technique used to compute the subordinate characteristic graphs of an attribute grammar's nonterminals [44]. Recently, Reps *et al.* [80] described a faster algorithm for computing summary edges. A summary edge is added if a path of control, flow, and summary edges exists in the called procedure from the corresponding formal-in vertex to the corresponding formal-out vertex. Note that the addition of a summary edge in procedure Q may complete a path from a formal-in vertex to a formal-out vertex in Q's PDG, which in turn may enable the addition of further summary edges in procedures that call Q.

Procedure dependence graphs are connected to form an SDG using three new kinds of edges:

1. A *call* edge is added from each call-site vertex to the corresponding procedure-entry vertex.
2. A *parameter-in* edge is added from each actual-in vertex at a call site to the corresponding formal-in vertex in the called procedure.
3. A *parameter-out* edge is added from each formal-out vertex in the called procedure to the corresponding actual-out vertex at the call site.

Figure 8 shows an example system and the corresponding SDG. (In Fig. 8, as well as in the remaining figures in this article, the edges representing control dependences are not labeled; all such edges would be labeled **true.**)

Interprocedural slicing can be defined as a reachability problem using the SDG, just as intraprocedural slicing is defined as a reachability problem

```
procedure Main
  sum := 0
  i := 1
  while i < 11 do
     call A (sum, i)
  od
  print(sum)
end

procedure A (x, y)
  call Add (x, y)
  call Increment (y)
return

procedure Add (a, b)
  a := a + b
return

procedure Increment (z)
  call Add (z, 1)
return
```

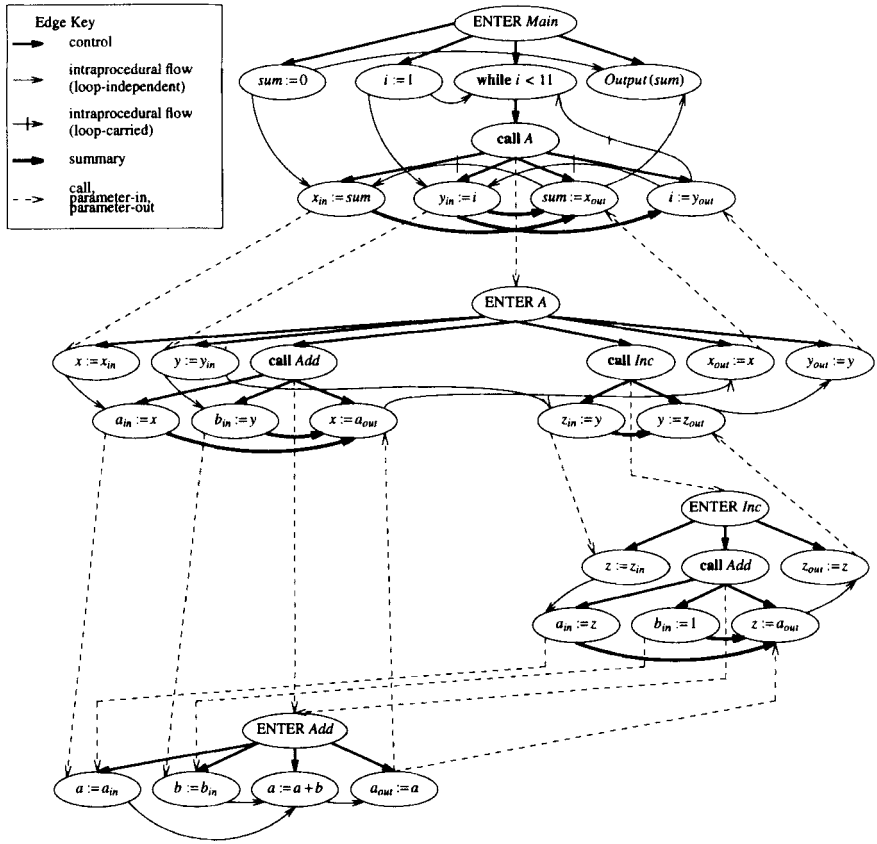

FIG. 8. Example system and its SDG.

using the PDG. The slices obtained using this approach are the same as those obtained using Weiser's interprocedural slicing method [93]. However, his approach does not produce slices that are as precise as possible, because it considers paths in the graph that are not possible execution paths. For example, there is a path in the graph shown in Fig. 8 from the vertex of procedure *Main* labeled "$x_{in} := sum$" to the vertex of *Main* labeled "$i := Y_{out}$." However, this path corresponds to procedure *Add* being called by procedure *A*, but returning to procedure *Increment*, which is not possible.

The value of i after the call to procedure A is independent of the value of *sum* before the call, and so the vertex labeled "$x_{in} := sum$" should not be included in the slice with respect to the vertex labeled "$i := Y_{out}$" Figure 9 shows this slice.

To achieve more precise interprocedural slices, an interprocedure slice with respect to vertex s is computed using two passes over the graph.

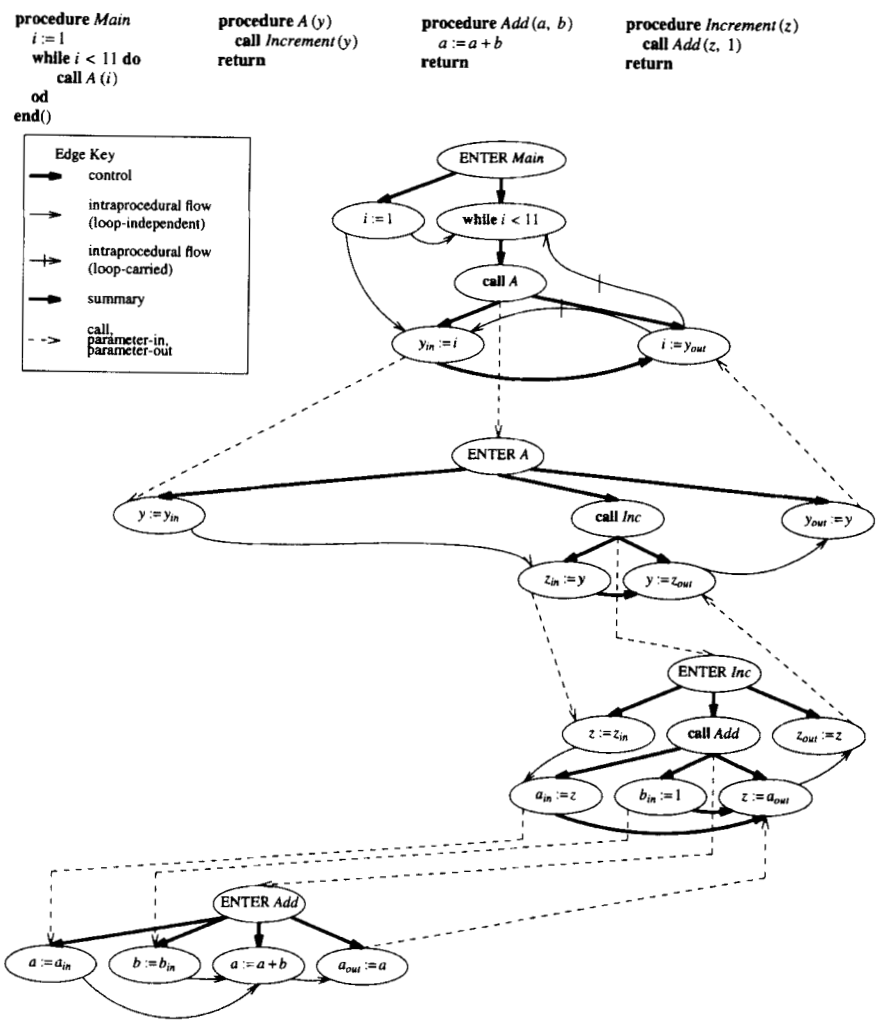

FIG. 9. The SDG from Fig. 8 sliced with respect to the formal-out vertex for parameter z in procedure *Increment*, together with the system to which it corresponds. Note that this slice correctly excludes the vertex labeled "$x_{in} := sum$" in Fig. 8.

Summary edges permit movement across a call site without having to descend into the called procedure; thus, there is no need to keep track of calling context explicitly to ensure that only legal execution paths are traversed. Both passes operate on the SDG, traversing edges to find the set of vertices that can reach a given set of vertices along certain kinds of edges. Informally, if s is in procedure P, then pass 1 identifies vertices that reach s and are either in P itself or procedures that (transitively) call P. The traversal in pass 1 does not descend into procedures called by P or its callers. Pass 2 identifies vertices in called procedures that induce the summary edges used to move across call sites in pass 1.

The traversal in pass 1 starts from s and goes backward (from target to source) along flow edges, control edges, call edges, summary edges, and parameter-in edges, but *not* along parameter-out edges. The traversal in pass 2 starts from all vertices reached in pass 1 and goes backward along flow edges, control edges, summary edges, and parameter-out edges, but *not* along call or parameter-in edges. The result of an interprocedural slice consists of the sets of vertices encountered during by pass 1 and pass 2, and the set of edges induced by this vertex set. A worklist algorithm for finding the vertices of an interprocedural slice is stated in [44]. The (full backward) interprocedural slice of graph G with respect to vertex set S, denoted by $Slice(G, S)$, consists of the sets of vertices identified by pass 1 and pass 2, and the set of edges induced by this vertex set.

$Slice(G, S)$ is a subgraph of G. However, unlike intraprocedural slicing, it may not be feasible (i.e., it may not be the SDG of any system). The problem arises when $Slice(G, S)$ includes mismatched parameters: Different call sites on a procedure include difference parameters. There are two causes of mismatches: Missing actual-in vertices and missing actual-out vertices. Making such systems syntactically legal by simply adding missing parameters leaves semantically unsatisfactory systems [17]. To include the program components necessary to compute a safe value for the parameter represented at missing actual-in vertex v, the vertices in the pass 2 slice of G taken with respect to v must be added to the original slice. A pass 2 slice includes the minimal number of components necessary to produce a semantically correct system. The addition of pass 2 slices is repeated until no further actual-in vertex mismatches exist.

The second cause of parameter mismatches is missing actual-out vertices. Because missing actual-out vertices represent dead code no additional slicing is necessary. Actual-out mismatches are removed by simply adding missing actual-out vertices to the slice.

A system can now be obtained by projecting the statements of the original system that are in the original slice or added by the preceding two steps.

These statements appear in the same order and at the same nesting level as in the original system. The details of this algorithm are given in [17].

2.2.3 *Interprocedural Slicing in the Presence of Call-by-Reference Parameter Passing and Aliasing*

The definitions of the system dependence graph and interprocedural slicing assume that parameters are passed by using value-result parameter passing. The same definitions hold for call-by-reference parameter passing in the absence of aliasing; however, in the presence of aliasing, some modifications are required. Two extreme methods for handling aliasing include transforming the system into an aliasing-free system and generalizing the definition of flow dependence. Translation is done by creating a copy of a procedure for each possible aliasing configuration that it may be called under. Because the number of aliasing configurations is potentially exponential, the cost of this transformation may, in the worst case, be exponential in the maximum number of formal parameters associated with any one procedure.

Generalizing the definition of flow dependence makes the pessimistic assumption that any aliases that exist during a particular call to a procedure *may* exist during all calls to the procedure. Such aliases are referred to as *may* aliases. This requires the use of generalized definitions for flow dependence. For example, a flow dependence edge connects vertex v to vertex u iff all of the following hold:

1. v is a vertex that defines variable x.
2. u is a vertex that uses variable y.
3. x and y are potential aliases.
4. Control can reach u after v via a path in the control-flow graph along which there is no intervening definition of x or y.

Note that clause (4) does not exclude there being definitions of other variables that are potential aliases of x or y along the path from v to u. An assignment to a variable z along the path from v to u only over-writes the contents of the memory location written by v if x and z refer to the same memory location. If z is a potential alias of x, then there is only a *possibility* that x and z refer to the same memory location; thus, an assignment to z does not necessarily over-write the memory location written by v, and it may possible for u to read a value written by v.

The first solution produces more precise (smaller) slices than the second at the expense of transforming the system. It is possible to consider interme-

diate solutions to the problem of slicing in the presence of aliasing. Binkley [16] presents an algorithm that is parameterized by a set of aliasing information. The more precise this information, the more precise the slice. In the case of exact information, the same slice is produced as by the transformation approach without replicating procedures. In the case of a maximal approximation (imprecise information), the same slice if obtained as by the generalized dependence approach. In between is a range of possible slices differing only in their precision.

2.3 Dynamic Slicing as a Data-Flow Problem

Korel and Laski [49] introduced the idea of dynamic slicing. Their solution, patterned after Weiser's static slicing algorithm, solves the problem using data-flow equations. A dynamic slice differs from a static slice in that it makes use of information about a particular execution of a program. Thus, a dynamic slice contains "all statements that *actually* affect the value of a variable at a program point for a *particular* execution of the program" rather than "all statements that *may* affect the value of a variable at a program point for any arbitrary execution of the program" [49].

Most dynamic slices are computed with respect to an *execution history* (called a *trajectory* in [49]). This history records the execution of statements as the program executes. The execution of a statement produces an occurrence of the statement in the execution history. Thus, the execution history is a list of statement occurrences.

Example. Two example execution histories are shown in Fig. 10. Superscripts are used to differentiate between the occurrences of a statement. For example, statement 2 executes twice for the second execution producing occurrences 2^1 and 2^2. ■

Korel and Laski define a dynamic slice, taken with respect to a set of

Statement Number	Program
1	**read**(N)
2	**for** $i = 1$ **to** N **do**
3	$a = 2$
4	**if** $c1$ **then**
5	**if** $c2$ **then**
6	$a = 4$
	else
7	$a = 6$
	fi
	fi
8	$z = a$
	od
9	**print**(z)

Execution History 1
Input N=1, $c1$ and $c2$ both true. $<1^1, 2^1, 3^1, 4^1, 5^1, 6^1, 8^1, 2^2, 9^1>$

Execution History 2
Input N=2, $c1$ and $c2$ false on the first iteration and true on the second.
$<1^1, 2^1, 3^1, 4^1, 8^1, 2^2, 3^2, 4^2, 5^1, 6^1, 8^2, 2^3, 9^1>$

FIG. 10. Two execution histories.

```
read(N)                          Execution history of slice
for i = 1 to N do
  a = 2                          <1^1, 2^1, 3^1, 2^2, 3^2>
od
```

FIG. 11. A dynamic slice of the program shown in Fig. 10 and its execution history.

variables V, an input I, and a point P in the execution history (obtained by running the program on I), as a reduced executable program. The execution history for the execution of this program on input I must satisfy the *slice sublist* property. Intuitively this property is satisfied if the execution history of the slice is equivalent to the execution history of the original program after removing occurrences of statement not in the slice.

Figure 11 shows the Korel and Laski slice of the program shown in Fig. 10 taken with respect to $(\{a\}, 2, 3^2)$. Notice that this slice imprecisely includes 3^1, which does not affect the computation at 3^2. Why this occurrence is needed in the Korel and Laski framework and how Agrawal and Horgan remove it are discussed at the end of this section.

To formalize the notion of a dynamic slice, we consider the relationship between the execution histories of the program and its slice (on the same input). The execution history of the slice should be obtained by removing occurrences from execution history of the original program. To do this we must remove occurrences of statements not in the slice and remove all occurrences after the occurrence with respect to which the slice was taken.

Formally, we make use of three operators:

1. $collect(list, predicate) = [l \in list \mid predicate(l) = \textbf{true}]$
2. $front(list, l_i) = [l_j \in list \mid j <= i]$
3. $occurrence\_of(l_i, P) = \textbf{true}$ iff l_i is an occurrence of a statement of P.

Definition 7: Dynamic Slice. Program P' is the slice of program P taken with respect to (V, I, p) if L and L' are the execution histories for P and P', respectively, p' is the occurrence of p in L', and the following property is satisfied:

$$front(L', p') = collect(front(L, p), \lambda l.occurrence\_of(l, P')) \quad \blacksquare$$

Example. For the slice taken with respect to $(\{a\}, 2, 3^1)$ of the program shown in Fig. 10 we have $(<1^1, 2^1, 3^1, 2^2, 3_2>, 3_1) = <1^1, 2^1, 3^1>$ and

$$collect\ (front\ (<1^1, 2^1, 3^1, 4^1, 8^1, 2^2, 3^2, 4^2, 5^1, 6^1, 8^2, 2^3, 9^1>, 3^1), \lambda l.occurrence\_of(l, P')) = collect(<1^1, 2^1, 3^1>, \lambda l.occurrence\_of(l, P')) = <1^1, 2^1, 3_1>$$

While for the slice with respect to $(\{a\}, 2, 3^2)$

$$front\ (< 1^1, 2^1, 3^1, 2^2, 3^2 >, 3^2) = < 1^1, 2^1, 3^1, 2^2, 3^2 >.$$

and

$$collect(front(< 1^1, 2^1, 3^1, 4^1, 8^1, 2^2, 3^2, 4^2, 5^1, 6^1, 8^2, 2^3, 9^1 >, 3^2), \lambda l.occurrence\_of(l, P')) = collect(< 1^1, 2^1, 3^1, 4^1, 8^1, 2^2, 3^2 >, \lambda l.occurrence\_of(l, P')) = < 1^1, 2^1, 3^1, 2^2, 3^2 >.$$ ■

Dynamic slices are computed from three data-flow relations computed from the program. The first two capture the flow and control dependences. Unlike static slicing, these definitions refer to the execution history; thus, they capture dependences that actually happened in the particular execution of the program rather than dependences that may occur in some execution of the program as is the case with static slicing. The final relation is explained later.

The first definition captures flow dependences that arise when one occurrence represents the assignment of a variable and another a use of that variable. For example, in Fig. 10 when $c1$ and $c2$ are both false, there is a flow dependence from s_3 to s_8.

Definition 8: Definition Use (*DU*). $v^i DU\ u^j \Leftrightarrow v^i$ appears before u^j in the execution history and there is a variable x defined at v^i, used at u^j, but not defined by any occurrence between v^i and u^j. ■

The second definition captures control dependence. The only difference between this definition and the static control dependence definition is that multiple occurrences of predicates exist. Consequently, care must be taken to avoid a statement appearing dependent on a predicate from an earlier iteration of a loop.

Definition 9: Test Control (*TC*). $v^i TC\ u^j \Leftrightarrow u$ is control dependent on v (in the static sense) and for all occurrences w^k between v^i and u^j, w is control dependent on v. ■

The definition of a dynamic slice requires the use of $front(L', p') = collect(front(L, p), \lambda l.occurrence\_of(l, P'))$. The preceding two relations are insufficient to ensure this. For example, the slice obtained from the program in Fig. 10 taken with respect to $(\{a\}, 2, 3^2)$ using only the preceding two relations is $< 1^1, 2^1, 2^2, 3^2 >$, which omits 3^1. In this example the omission would be benign, but in other examples the slice would not have the correct execution history. Korel and Laski solve this problem by including the following relation. Note that this produces a conservative solution to the problem. That is, some dynamic slices are bigger than they need to be.

Definition 10: Identity Relation (*IR*). $v^i\ IR\ u^j \Leftrightarrow v = u.$ ■

The relations *DU*, *TC*, and *IR* are used to formulate the algorithm for a dynamic slicing by computing an ever-growing approximation to the occurrences in the slice. Let E be the execution history produced for program P when run on input I. In the following two equations, only the *front* of E is of interest to the dynamic slice, since only these occurrences may affect the point where the slice originates.

The first approximation to the slice taken with respect to (V, I, l^i) contains the direct control and data influences: $S^0 = \{v^j \in front(E, l^i) \mid v^j\ TC\ l^i\} \cup \{v^j \in front(E, l^i) \mid x \in V \wedge x$ is defined at v^j but not defined by any occurrence between v^j and $l^i\}$.

The slice is found by iterating the following until a fixed point is reached: $S^{i+1} = S^i \cup \{v^j \in front(E, l^i) \mid \exists u^k \in S^i\ s.t.\ v^j\ (DU \cup TC \cup IR)\ u^k\}$. The iteration from earlier must terminate since E is finite and bounds each S^i. To complete the slice, it is necessary to include the occurrence with respect to which the slice was taken. Finally, the sliced program P' is obtained by projecting out of P those statements that have occurrences in the fixed point solution.

Example. The dynamic slice of execution history 2 from Fig. 10 taken with respect to $(\{a\}, 2, 3^1)$ is computed as follows

$$
\begin{aligned}
DU &= \{(1^1, 2^1)(3^1, 8^1)(6^1, 8^2)(8^2, 9^1)\} \\
TC &= \{(2^1, 3^1)(2^1, 4^1)(2^1, 8^1)(2^1, 3^2)(2^1, 4^2)(2^1, 8^2)(2^2, 3^2)(2^2, 4^2)(2^2, 8^2) \\
&\quad (4^2, 5^1)(5^1, 6^1)\} \\
IR &= \{(2^1, 2^2)(2^1, 2^3)(2^2, 2^3)(3^1, 3^2)(4^1, 4^2)(8^1, 8^2)\} \\
S^0 &= \{2^1\} \\
S^1 &= \{1^1, 2^1\} \\
S^2 &= \{1^1, 2^1\} = S_1; \text{ thus the iteration ends.} \\
S &= \{3^1\} \cup \{1^1, 2^1\} = \{1^1, 2^1, 3^1\}.
\end{aligned}
$$

■

Similar to static slicing, handling unstructured control flow requires modifying the definition of *control dependent* as used in the definition of *TC*. Unlike static slicing, the handling of different data types can be done more precisely in a dynamic slice. First consider arrays. Because the subscript value is known at run time, the ambiguity of array accesses in static slicing is gone. The only complication this raises is that different occurrences of a statement may assign different variables (for simplicity, we consider each array element to be a different variable). Records are similarly handled by treating each component as a separate variable. Finally, consider dynamically allocated memory. This can also be handled by giving each newly allocated block of memory a pseudo name. At the end of the next section

we describe how Agrawal and Horgan replace the notion of (pseudo) variable name to improve dynamic slicing in debugging.

2.4 Dynamic Slicing as a Graph-Reachability Problem

Agrawal and Horgan presented the first algorithms for finding dynamic slices using dependence graphs [5]. We first consider two simply dynamic slicing algorithms that are imprecise. We then consider two exact algorithms that differ only in their space complexity. The initial description of all four algorithms assumes scalar variables. The extensions necessary to handle complex data structures including, for example, (unconstrained) pointers, arrays, records, and unions are considered at the end of this section.

The first two algorithms both mark some portion of a PDG as "executed." The first marks executed vertices and the second marks executed edges. Both algorithms suffer because they summarize in one place (a vertex or an edge) all the times a statement or dependence edge between statements was executed. The first algorithm initially labels all vertices in the PDG as "unexecuted." As the program runs, whenever a statement is executed, its corresponding vertex is marked as "executed." After execution the slice is computed by applying the static slicing algorithm restricted to only marked vertices (and the edges that connect them). Thus, unexecuted vertices will not be in the dynamic slice.

As illustrated in Fig. 12 by slice 1, this approach produces imprecise slices because it is possible for a vertex to be marked executed even though it does not actually affect a given computation. For slice 1, s_3 is executed, but the assignment at s_6 overwrites the value written to *a*. Therefore, s_3 need not be in the dynamic slice.

The second algorithm marks "executed edges." This produces more precise answers by leaving out statements that were executed, but had no influence on the variables in the slice (the corresponding edges were not "executed"). Its imprecision comes in loops where different iterations execute different edges. In slice 1 shown in Fig. 12, the marking of edges allows

Slice 1: slice on z at s_9 for the input $N=1$, where *c1* and *c2* both true:
static slice contains s_1–s_9
dynamic slice (marking nodes) contains s_1–s_6, s_8, s_9
dynamic slice (marking edges) contains s_1, s_2, s_4–s_6, s_8, s_9

Slice 2: slice on z at s_9, for input $N=2$, where *c1* and *c2* false on the first iteration and true on the second:
static slice contains s_1–s_9
dynamic slice (marking nodes) contains s_1–s_6, s_8, s_9
dynamic slice (marking edges) contains s_1–s_6, s_8, s_9

FIG. 12. Two dynamic slices of the program of Fig. 10 that show the limitations of the first two dynamic slicing algorithms.

the algorithm to leave out s_3, because the flow dependence edge from s_3 to s_8 is never executed. However, for slice 2, this edge is executed during the first iteration of the loop. Since the second iteration overwrites the value of a, s_3 need not be in the dynamic slice. The problem is that different iterations require the marking of different edge *occurrences.* Summarizing all occurrences on a single edge introduces imprecision.

Example. Figure 12 compares static slicing with these two dynamic slicing algorithms for two different inputs. (Figure 13 shows the PDG for this program.) The static slice taken at (the vertex representing) statement s_9 with respect to z contains the entire program because all three assignments to a may reach the use at statement s_8. The node-marking dynamic slicing algorithm produces a smaller slice for both inputs because s_7 does not execute in either case. These slices, however, unwantedly include s_3, which does execute, but which does not affect the computation of z. The edge-marking algorithm correctly handles this in slice 1, because the flow dependence edge from s_3 to s_8 is not executed. However, the weakness of the edge-marking algorithm is shown by slice 2: Although the assignment at s_2 does not affect the output value of z, this flow edge is executed by the first iteration of the loop. Because it is marked executed, s_2 is included in the slice. ■

To omit statements in loops like s_3, it is necessary to have multiple occurrences of the vertices and edges in the loop. This is captured by the *execution history* of a program for a given input. For example, Slice 2 of the program in Fig. 12 produces the execution history $< 1, 2^1, 3^1, 4^1, 8^1,$

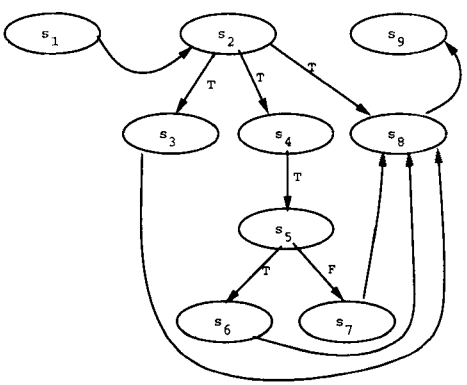

FIG. 13. The PDG for the program shown in Fig. 10.

2^2, 3^1, 4^2, 5^2, 6^2, 8^2, 2^3, 9 > where the superscripts are used to denote different executions of the same statement.

A dynamic slice can now be defined in terms of a variable, an execution history, and an occurrence of a statement in the execution history. The slice contains only those statements whose execution had some effect on the value of the variable at the occurrence of the statement in the execution history. To obtain this slice a *dynamic dependence graph* (DDG) is produced from the execution history. A dynamic dependence graph has a vertex for each occurrence of a statement in the execution history and contains only executed edges. Because a DDG separates the occurrences of the executed vertices and edges, a vertex in a loop may have multiple occurrences, which can have different incoming dependence edges. This removes the imprecision in the two simple approaches.

Control dependence edges of the DDG are copies of the control dependence edges from the static dependence graph. There is a single dynamic flow dependence for each variable v referenced at a node n. The source of this edge is computed from the *dynamic reaching definitions* (DRDs), which are in turn computed from the execution history as follows:

$DRD(var, empty) = \emptyset$.
$DRD(var, < previous\_history \mid last\_node >) =$

$$\begin{cases} \{last\_node\} & \text{if } var \in def(last\_node) \\ DRD(var, previous\_history) & \text{otherwise.} \end{cases}$$

Example. Figure 14 shows the DDG for slice 2 of the program shown in Fig. 12. This graph contains two occurrences of s_8. The first has an

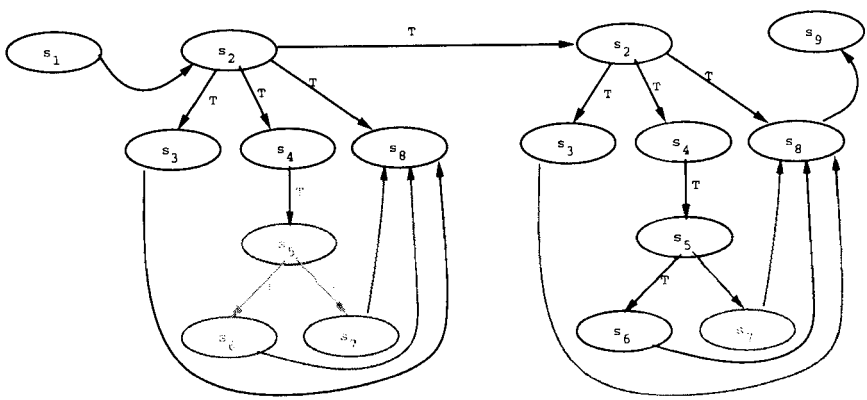

FIG. 14. The DDG for slice 2 in the example shown in Fig. 12.

incoming flow dependence edge from s_3, whereas the second has an incoming flow dependence edge from s_6. Since the only occurrence of s_9 has an incoming edge from the second occurrence of s_8, s_6 and not s_3 is included in the slice. ■

The disadvantage of this approach is its space requirement. Since a loop may execute an unbounded number of times, there may be an unbounded number of vertex occurrences. This is clearly unacceptable and, it turns out, unnecessary. A dynamic slice is a subset of the original program; consequently, there can be only a finite number of slices (subsets). The final dynamic slicing algorithm, which computes the same slices as the third algorithm, exploits this fact to limit the size of the dynamic dependence graph.

The fourth algorithm considers each new vertex occurrence v as the DDG is built. If a suitable vertex occurrence u exists in the DDG then v is merged into u. Vertex occurrence u is suitable if its slice is the same as the slice of the new vertex occurrence. That is, the statements whose occurrences affect u are the same as the statements that affect v. Note that since the slice is a projection of the DDG back on to the original program, it is possible to combine vertices that are not created from the same statement.

The algorithm maintains three sets: *DefinitionNode,* which maps a variable's name to the last vertex occurrence that defines it; *PredicateNode,* which maps a control statement to its most recent occurrence in the DDG; and *ReachingStatements,* which, for each node n, contain all the statements of the original program with an occurrence that reaches n. The slice with respect to an occurrence of statement s is simply those statements in *ReachingStatements(s),* when the occurrence of s is created.

2.4.1 Dynamic Slicing of Programs with Unconstrained Pointers

Agrawal and DeMillo [4] extended the notion of dynamic slicing to programs that contain unconstrained (C-like) pointers. The technique applies also to arrays, constrained (Pascal-like) pointers, records, and other data structures.

What makes unconstrained pointers difficult is the loss of the 1–1 mapping from variables assigned and used and from *memory locations* assigned and used. This is no longer true in the presence of more complex data structures. Although aggregates such as records can be handled by treating each field as a separate variable, and even array elements can be treated as separate elements, since dynamic slicing has access to the run-time index value, pointers present a particularly difficult problem. If we ignore "pointer laun-

dering" through variant records, *constrained* pointers, such as those found in Pascal, always point to a nameable object of a particular type. Special names are given to objects allocated from the heap. As with records and arrays, run-time information allows us to identify the particular object pointed to by a given pointer. In contrast, *unconstrained pointers,* such as those found in C, may use or modify arbitrary (unnamed) memory locations.

This forces us to generalize first the notion of a variable (*var* in the proceeding definition of a DRD) to *memory cells.* Each cell is composed of a starting address and a length. A flow dependence exists between a node that modifies $cell_1$ and a node that references $cell_2$ if $cell_1$ and $cell_2$ overlap. This occurs when there is a nonempty intersection of the set of addresses $cell_1.start, \ldots, cell_1.start + cell_1.length$ and $cell_2.start, \ldots, cell_2.start + cell_2.length$. For example, if $cell_1$ represents an assignment to a structure and $cell_2$ represents a use of a field in this structure then the two cells overlap. Notice that an assignment to a field of the structure may only modify part of the cell (the same is true of assignments to an element of an array). In the following definition, the function $PreCell(cell_1, cell_2)$ denotes the part of $cell_1$ before $cell_2$. Likewise, $PostCell(cell_1, cell_2)$ denotes the part of $cell_1$ after $cell_2$.

Definition 11: DRD in the Presence of Unconstrained Pointers. Let $cell' = def(last\_node)$.

$$DRD(cell, empty) = \emptyset$$
$$DRD((address, 0), history) = \emptyset$$
$$DRD(cell, < previous\_history \mid last\_node >)$$

$$= \begin{cases} DRD(cell, previous\_history) & \text{if } cell \cap cell' = \emptyset \\ last\_node \cup DRD(PreCell(cell, cell'), previous\_history) & \\ \cup\ DRD(PostCell(cell, cell'), previous\_history) & \text{otherwise} \end{cases}$$ ■

This technique works well when dealing with the kind of error shown in the following code (note that different compilers may lay memory out differently):

```
{
 int i, j, a[4];

 j = 2;
 for (i=0; i<=4; i++)
    a[i] = 0;          /* incorrectly assigns j=0
                          when i = 4 */
 print j;
}
```

When $i = 4$, the cell defined by `a[i] = 0` and the cell for j overlap (they are identical in this example). A static slice with respect to j at the end of the program would only include the assignment $j = 2$. However, the dynamic slice using the preceding definition of a dynamic data definition includes the assignment "$a[i] = 0$" and the enclosing *for* loop, an indication that j is getting clobbered by the loop.

2.5 Alternative Approaches to Computing Program Slices

2.5.1 *Denotational Program Slicing: Functional Semantics*

Hausler [35] has developed a denotational approach for slicing structured programs. This approach uses the functional semantics of the "usual" restricted structured language; one with scalar variables, assignment statements, *if-then-else* statements, and *while* statements. The Mills semantics [56] is defined for the language; the meaning of the program is determined by a mapping from the variables to values.

In the Mills semantics, programs are constructed by composition of statements (i.e., functions from state to state). This permits the definition of a *sliceable subprogram:* any sequence of statements with the last j statements deleted. Thus slices can be taken at arbitrary points in the program.

The function

$$\alpha : \textit{statements} \times \textit{variables} \rightarrow \textit{variables}$$

captures the relevant sets, whereas the function

$$\delta : \textit{statements} \times \textit{variables} \rightarrow \textit{statements}$$

captures the slice. These two functions are defined semantically for each language construct. This yields a precise "Millsian" slice; moreover, it gives primitive recursive finite upper bounds on the number of times repetitive statements must be iterated to obtain the slice. These bounds are linear in the number of assignment statements in the program.

2.5.2 *Denotational Program Slicing: Descriptive Semantics*

Venkatesh [87] also looked at denotational slicing with the aim of separating semantically based definitions of a program slice from the justification of the algorithm to compute the slice. He has constructed a three-dimensional framework for the comparison and analysis of the definitions of a slice:

1. Executable or closure[5]
2. Forward or backward
3. Static or dynamic

and then gives semantic definitions of the eight combinations.

In [87] the idea of "contamination" was introduced as an extension to the usual semantics of the language in order to clarify the differences of the concepts. This notion is further elaborated on in [30] as a form of error propagation to slice functional programs. In both instances, contaminated values are tracked via the semantics; in the end all contaminated expressions are those that are in the forward slice.

Tip [85] gives an alternative characterization using four criteria:

1. Computation method: data flow, functional, or graph reachability
2. Interprocedural solution or not
3. Control flow: structured or arbitrary
4. Data types: scalars, composites, pointers.

2.5.3 *Information Flow Relations*

Bergeretti and Carré [13] construct three binary information flow relations on a structured subset of a Pascal-like language. These relations are associated with each program statement (and, hence, inductively over the entire language). The first relation, λ, over $V \times V$, where V is the set of variables of the program, associates values of program variables on entry to a statement, S, with values of variables on exit from S. This can be loosely interpreted as "the value of v on entry to S *may be used* in the evaluation of the expression e in S." This relation is a formalization of the results of Denning and Denning [23] in secure information flow.

The second relation, ρ, also over $V \times V$, associates values of variables on entry to statement S with the value(s) of the expression parts in S. That is, "the value of v on entry to S *may be used* in obtaining the value w on exit from S." The entry value of v may be used in obtaining the value of some expression e in S, which in turn may be used in obtaining the exit value of w.

The third relation, μ, over $E \times V$ where E is the set of expressions in the program, associates an expression e with a variable v for statement S iff "a value of expression e in S *may be used* in obtaining the value of the variable v on exit from S." For example, if S is the assignment statement "$a := b + c$," then

[5] "Closure" comes from the graph-theoretic method used to compute the slice.

$$\lambda(S) = \{(b, a), (c, a)\},$$
$$\rho(S) = \{(b, a), (c, a)\} \cup \{(v, v) - (a, a) \mid v \in V\},$$
$$\mu(S) = \{(b + c, a)\}.$$

Transitive closure of the μ relation permits construction of a *partial program* associated with a variable. This partial program is a program slice taken with respect to the variable at the last statement of the program. Relation μ is related to the edges of a dependence graph. For example, it need only be computed once, after which a program slice can be computed in linear time.

2.5.4 Parametric Program Slicing

Parametric program slicing [25] uses graph rewriting to compute *constrained* slices. The constraint refers to the amount of input available. A fully constrained slice (where input has a fixed constant value) is a dynamic slice, while a fully unconstrained slice is a static slice. A partially constrained slice is computed when some inputs have known values. The resulting slice is smaller than a static slice, but does not require complete execution of the program as with a dynamic slice.

Constrained slices are computed using a term graph rewriting system [9]. As the graph is rewritten, modified terms and subterms are tracked. As a result, terms in the final (completely rewritten) graph can be tracked back to terms in the original graph. This identifies the slice of the original graph that produced the particular term in the final graph. A minimal amount of syntactic postprocessing is necessary to convert this "term slice" into a syntactically valid sliced program.

2.5.5 Dynamic Slicing Using Dependence Relations

Gopal [31] describes a technique for computing dynamic slices using *dependence relations.* This approach abstracts from the program three relations at each statement S:

1. S_v, the dependence of statement S on the input value of variable v.
2. v_s, the dependence of output variable v on statement S.
3. v_u, the dependence of output variable v on the input value of variable u.

Rules are given for different statement kinds (e.g., assignment and conditional statements) and for sequences of statements. For example, the rules for the composition of statements S^1 and S^2 are as follows ($\circ$ represents the composition operator):

1. $S_v \equiv S_v^1 \cup (S_v^2 \circ v_u^1)$
2. $v_S \equiv v_S^2 \cup (v_u^2 \circ v_s^1)$
3. $v_u \equiv (v_s \circ S_v) \cup (S_v^2 \cap S_v^1)$.

2.5.6 Parallel Slicing

Danicic *et al.* [33] introduce a parallel algorithm for computing backward, static slices. This is accomplished by converting the CFG into a network of concurrent processes. Each process sends and receives messages that name the relevant sets of variables. The significant contribution of this work is that the algorithm outputs the *entire* set of criteria which would yield the computed slice. Thus the set of all criteria of a given program is partitioned into equivalence classes, with the slice itself used as the partitioning relation.

2.5.7 Value Dependence Graphs

The *value dependence graph* (VDG) [88] is a data-flow-like representation that evolved from an attempt to eliminate the control-flow graph as the basis of the analysis phase and using *demand* dependences instead. The VDG is a representation that is independent of the names of values, the locations of the values, and when the values are computed. It is a functional representation that expresses computation as value flow. A value is computed *if it is needed.* Thus, VDG requires explicit representation of stack and heap allocators, I/O ports, etc., so that the value can be obtained. Loops are represented as function calls, so no backward pointing edges are required, as in the CFG. The VDG has two advantages that make it suitable for program slicing: All operands are *directly* connected to the inputs (via the functional semantics) and the computation is expressed as value flow, so a single VDG represents the slices for every possible computation. The drawback to this approach is that points of computation are lost; values are the only sliceable objects.

3. Applications of Program Slicing

This section describes how program slicing is used in a collection of application domains. In applying slicing to these domains, several variations on the notions of program slicing as described in Section 2 are developed. The order of this section in not necessarily the historical order in which the problems were addressed. Rather, they are organized to facilitate presentation. For example, the differencing techniques described in Section 3.1 grew out of the integration work described in Section 3.2.

3.1 Differencing

Programmers are often faced with the problem of finding the differences between two programs. Algorithms for finding *textual* differences between programs (or arbitrary files) are often insufficient. Program slicing can be used to identify *semantic* differences between two programs. There are two related programs differencing problems:

1. Find all the components of two programs that have different behavior.
2. Produce a program that captures the semantic differences between two programs.

Dependence graph solutions to both problems have been given. The only reason for not using the data-flow approach is efficiency; the solutions require multiple slices of the same program, which can be done in linear time using dependence graphs.

For programs *old* and *new*, a straightforward solution to problem 1 is obtained by comparing the backward slices of the vertices in *old* and *new*'s dependence graphs G_{old} and G_{new}. Components whose vertices in G_{new} and G_{old} have isomorphic slices (see [41] for a definition of isomorphic slices) have the same behavior in *old* and *new* [82]; thus, the set of vertices from G_{new} for which there is no vertex in G_{old} with an isomorphic slice *safely approximates* the set of components *new* with changed behavior. This set is *safe* because it is guaranteed to contain all the components with different behavior. It is (necessarily) an *approximation* because the exact differencing problem is unsolvable.

We call the vertices in G_{new} with different behavior than in G_{old} the set of *affected points*. The complexity of the straightforward solution for finding affected points outlined earlier is cubic in the size of G_{new} (slice isomorphism can be determined in linear time [41]). This set can be efficiently computed in linear time using a single forward slice starting from the set of *directly affected points:* those vertices of G_{new} with different incoming dependence edges than in G_{old} [19].

A solution to the second differencing problem is obtained by taking the backward slice with respect to the set of affected points. For programs with procedures and procedure calls, two modifications are necessary: First, the techniques described at the end of Section 2.2.2 are required to ensure the resulting program is executable. Second, this solution is overly pessimistic: Consider a component c in procedure P that is called from two call sites c_1 and c_2. If c is identified as an affected point by a forward slice that enters P through c_1, then, assuming there is no other connection, we want to include c_1 but not c_2 in the program that captures the differences. However,

the backward slice with respect to c would include both c_1 and c_2. A more precise solution can be obtained by using a combination of the individual interprocedural slicing passes described in Section 2.2.2 [19].

3.2 Program Integration

The program integration operation concerns the problem of merging program variants [39, 19, 95]. Given a program *Base* and two variants, *A* and *B*, each created by modifying separate copies of *Base*, the goal of program integration is to determine whether the modifications interfere, and if they do not, to create an integrated program that incorporates both sets of changes as well as the portions of *Base* preserved in both variants.

The need for program integration arises in many situations:

- When a system is "customized" by a user and simultaneously upgraded by a maintainer, and the user desires a customized, upgraded version.
- When a system is being developed by multiple programmers who may simultaneously work with separate copies of the source files.
- When several versions of a program exist and the same enhancement or bug-fix is to be made to all of them.

The integration algorithm uses program differencing to identify the changes in variants *A* and *B* with respect to *Base*. Preserved components are those components that are not affected in *A* or *B*. This set is safely approximated as the set of components with isomorphic slices in *Base*, *A*, and *B*. A merged program is obtained by taking the graph union of the (dependence graph for) the differences between *A* and *Base*, the differences between *B* and *Base*, and the preserved components. This program is then checked for interference. Interference exists if the changes in variant *A* and variant *B* are incompatible. If there is no interference, a merged program is produced that captures the changed *behavior* of *A* and *B* along with the preserved *behavior* of all three programs.

An important property of the algorithm is that it is semantics based. Thus, the integration tool makes use of knowledge of the programming language to determine whether the changes made to *Base* to create the two variants have undesirable semantic interactions; only if there is no such interference will the tool produce an integrated program. The algorithm also provides guarantees about how the execution behavior of the integrated program relates to the execution behaviors of the base program and the two variants.

3.3 Testing

Software maintainers are faced with the task of regression testing: retesting software after a modification. This process may involve running the

modified program on a large number of test cases, even after the smallest of changes. Although the effort required to make a small change may be minimal, the effort required to retest a program after such a change may be substantial. Several algorithms based on program slicing have been proposed to reduce the cost of regression testing.

The following algorithms assume that programs are tested using test data adequacy criterion: a minimum standard that a test suite (a set of test cases) must satisfy. An example is the *all-statements* criterion, which requires that all statements in a program be executed by at least one test case in the test suite. Satisfying an adequacy criterion provides some confidence that the test suite does a reasonable job of testing the program [11, 75, 18].

Gupta *et al.* [32], present an algorithm for reducing the cost of regression testing that uses slicing to determine components affected transitively by an edit at point *p*. They consider a variety of different types of edits (statement addition, statement deletion, modification of the variables used in a statement, etc.) While some of these require simplified versions of the following procedure, in general two slices are used. The first slice is a backward slice from *p*. Definitions in this slice of variables used at *p* are recorded. The second slice is a forward slice also starting from *p*. Uses in this slice of variables defined at *p* are recorded. *Def-Use* pairs from a definition in the first slice to a use in the second are potentially affected by the change and must be retested.

Bates and Horwitz [11] present test case selection algorithms for the all vertices and the all flow edges test data adequacy criteria. The key to their algorithm is the notion of *equivalent execution patterns.* Two program components with equivalent execution patterns are executed by the same test cases [11]. Consider, for example, a component *old* from a tested program and component *new* of a modified version of this program. If test case *t* tests *old,* and *old* and *new* have equivalent execution patterns then test case *t* is guaranteed to test *new.* No new test case need be devised (even if *new* does not exist in the original program). The algorithms only select tests that test changed portions of the modified program.

Components with equivalent execution patterns are identified using a new kind of slice called a *control slice.* A control slice, which is essentially a slice taken with respect to the control predecessors of a vertex, includes the statements necessary to capture "when" a statement is executed without capturing the computation carried out at the statement.

The notion of equivalent execution patterns is too strong in the presence of procedures and procedure calls because it does not separate different calling contexts (i.e., different chains of call sites). Consider a simple program with two procedures, *main* and *P,* where *main* calls *P.* If another call to *P* is added to *main,* then the control slice for any component in *P* will

include this new call and therefore cannot be isomorphic with any control slice from the original program. Consequently, two such components cannot have equivalent execution patterns.

Calling context is more accurately accounted for by replacing equivalent execution patterns with the weaker notions of *common execution patterns* [18]. Components with common execution patterns have equivalent execution patterns in some calling context. These components are identified using another kind of slice called a *calling-context slice,* which applies the second pass of backward slicing algorithm described in Section 2.2.2 "back" through the sequence of call sites that makes up a calling context.

Program differencing can be used to further reduce the cost of regression testing by reducing the size of the program on which the tests must be run [15]. After a modification to a previously tested program, the resulting program is typically run on a large number of test cases to ensure the modification did not inadvertently affect other parts of the program. For a small change, the program produced using the program differencing techniques described in Section 3.1 is considerably smaller and consequently requires fewer resources to retest, especially when run on the reduced test set produced by any of the preceding algorithms.

3.4 Debugging

Program slicing was discovered as an operation performed by experienced programmers when debugging code [91, 89]. Programmers, given a piece of code with a bug in it, were asked to describe the code after removing the bug. They could reproduce certain "parts" of the code almost exactly, while others they could not. These parts were not continuous blocks of text (e.g., files, procedures, or functions), but rather they were what we now call program slices. Formalization of this debugging activity lead to the first algorithms for program slicing [89, 90].

Turning this around, a tool that computes program slices is a valuable aid in debugging. It allows the programmer to focus attention on those statements that contribute to a fault. In addition, highlighting a slice assists in uncovering faults caused by a statement that should be in a slice but is not.

Several kinds of slices are useful in debugging. First, dynamic slicing is one variation of program slicing introduced to assist in debugging [49, 50]. When debugging, a programmer normally has a test case on which the program fails. A dynamic slice, which normally contains less of the program than a static slice, is better suited to assist the programmer in locating a bug exhibited on a particular execution of the program. As seen in Section 2.4.1, dynamic slicing can even assist in finding bugs caused by invalid pointers or array subscripts.

Slicing is also useful in algorithmic debugging, which applies the following algorithm to the debugging process: Starting from an external point of failure (e.g., an arrant output value), the debugging algorithm localizes the bug to within a procedure by asking the programmer a series of questions. These questions relate to the expected behavior of a procedure. For example, "should *add*(4, 2) return 6?" Based on these answers, procedures that have the expected output are treated as working, while procedures that produce unexpected answers are "opened." This means the debugger attempts to determine if the calls in the procedure produce expected results. Algorithmic debugging terminates at a procedure with no calls or in a procedure in which all the calls produce the expected output.

One drawback of algorithmic debugging is that it asks questions about procedures that do not affect a buggy result. Program slicing can be of assistance here [46]: Any call not in the slice with respect to the buggy output can be ignored; it cannot affect the buggy result. Further, parameters that are not in the slice, even for a call that is, can also be ignored.

Debugging was also the motivation for *program dicing* and latter *program chopping*. Dicing uses the information that some variables fail some tests, while other variables pass all tests, to automatically identify a set of statements likely to contain the bug [62]. A program dice is obtained using set operations on one or more backward program slices. Some dices are more interesting than others. The interesting ones include the intersection of two slices, and the intersection of slice A with complement of slice B. The first dice, which identifies common code, is helpful in locating bugs when two computations are both incorrect assuming all incorrectly computed variables are identified and no program bug masks another bug [62]. This dice is also useful in ensuring software diversity in safety critical systems. If, for example, the computation of *trip-overtemperature-sensor* and *trip-overpressure-sensor* includes the same computation (often a function call) then this computation is in the dice taken with respect to the two *trip* signals. Such a computation is of interest in safety critical systems because a bug in this computation may cause both sensors to fail.

The second dice, which yields code unique to A, is helpful in locating bugs in computation on A if computation of B is correct. For example, consider a program that counts the number of words and characters in a file. If the final value of `character_count` is correct, but the final value of `word_count` is not, then the second kind of dice could be applied. In this case, it contains statements that affect the value of `word_count` but not the value of `character_count`. This implies that the looping and reading of characters from the file need not be considered.

The original work on dicing considered only backward slices. Incorporating forward slices increases the usefulness of dicing. For example, the notion

of *program chopping* identifies the statement that transmits values from a statement t to a statement s [45]: *chop*(t, s) includes those program points affected by the computation at program point t that affect the computation at program point s. A program chop is useful in debugging when a change at t causes an incorrect result to be produced at s. The statements in *chop*(t, s) are the statements that transmit the effect of the change at t to s. Debugging attention should be focused there. In the absence of procedures, *chop*(t, s) is simply the intersection of the forward slice taken with respect to t and the backward slice taken with respect to s and can be viewed as a generalized kind of program dice. The same is not true for interprocedural chopping [81].

As initially introduced, s and t must be in the same procedure P, and only components from P are reported. This was later generalized to allow s and t to be in different procedures and to contain components for procedures other than P [81]. It is interesting to note that for interprocedural chopping the dicing idea of intersecting a forward and backward slice is imprecise. Interprocedural versions of other set theoretic operations on slices that work with intraprocedural slices have eluded researchers [77]. Precise interprocedural chopping is addressed in [81].

3.5 Software Quality Assurance

Software quality assurance auditors are faced with a myriad of difficulties, ranging from inadequate time to inadequate computer-aided software engineering (CASE) tools [29]. One particular problem is the location of safety critical code that may be interleaved throughout the entire system. Moreover, once this code is located, its effects throughout the system are difficult to ascertain. Program slicing is applied to mitigate these difficulties in two ways. First, program slicing can be used to locate all code that contributes to the value of variables that might be part of a safety critical component. Second, slicing-based techniques can be used to validate *functional diversity* (i.e., that there are no interactions of one safety critical component with another safety critical component and that there are no interactions of nonsafety critical components with the safety critical components).

A design error in hardware or software, or an implementation error in software may result in a *common mode failure* of redundant equipment. A common mode failure is a failure as a result of a common cause, such as the failure of a system caused by the incorrect computation of an algorithm. For example, suppose that **X** and **Y** are distinct critical outputs and that **X** measures a rate of increase while **Y** measures a rate of decrease. If the computation of *both* of the rates depends on a call to a common

numerical differentiator, then a failure in the differentiator can cause a common mode failure of **X** and **Y.**

One technique for defending against common mode failures uses *functional diversity.* Functional diversity in design is a method of addressing the common mode failure problem in software that uses multiple algorithms on independent inputs. Functional diversity allows the same function to be executed along two or more independent paths.

One technique to solve this problem combines *fault-tree analysis* and program slicing. Once the system hazards have been identified, the objective of fault-tree analysis is to mitigate the risk that they will occur. One approach to achieving this objective is to use *system fault-tree analysis.* Under the assumption that there are relatively few unacceptable system states and that each of these hazards has been determined, the analysis procedure is as follows. The auditor assumes that a hazard has occurred and constructs a tree with the hazardous condition as the root. The next level of the tree is an enumeration of all the necessary preconditions for the hazard to occur. These conditions are combined with a logical AND and OR as appropriate. Then each new node is expanded "similarly until all leaves have calculable probability or cannot be expanded for some reason" [55].

System fault-tree analysis gives the auditor the subcomponents of the system that must be carefully examined. Part of this examination is the validation that there are no interactions with noncritical functions. The determination of the specific components that will be examined is up to the auditor. This information should be obtainable from the design documentation.

Slicing is used as an aid to validating safety as follows. First, the auditor uses system fault-tree analysis to locate critical components. The software that is invoked when a hazardous condition occurs is identified in the system. The auditor then locates the software variables that are the indicators of unsafe conditions. Program slices are extracted on these "interesting" variables. These slices can be used to validate that there are no interactions between critical components or with noncritical components using program dicing.

Program slices can also be used to assure diversity: Slices computed from the outputs of individual hazards can be examined to determine the logical independence of the events. For instance, if A and B are two critical conditions, the dice computed by intersecting the program slices on these wo conditions provides partial information on whether or not both conditions can occur simultaneously. If the dice is empty, then there is no way that the software can guarantee that both will not occur simultaneously there may be other ways the verify that both will not occur). If the dice

is not empty, inspection of the overlap *may* prove that both conditions cannot occur together (although the functional diversity of such computations is suspect).

These program projections can also be highlighted for more vigorous analysis, inspection, and testing. A static program slice can be further refined by examining the trajectory of specific inputs through the program; dynamic slices are used to observe individual instances of the computation. This simplifies the tedious task of the auditor and permits undivided attention to be focused on the analytic portions of the audit.

The utility of a slicing tool comes from automating the task of finding statements that are relevant to a computation. Without any tool, the software quality assurance auditor evaluating functional diversity would examine the program under consideration until outputs were identified that should be computed independently. The auditor would then try to verify independence by reading code.

Unravel [63] is a static program slicer developed at the National Institute of Standards and Technology as part of a research project. It slices ANSI-C programs. Its only limitations are in the treatment of *unions, forks,* and pointers to functions. The tool is divided into three main components: a source code analysis component to collect information necessary for the computation of program slices, a link component to link flow information from separate source files together, and an interactive slicing component that the software quality assurance auditor can use to extract program components and statements for answering questions about the software being audited.

3.6 Software Maintenance

Software maintainers are faced with the upkeep of programs after their initial release and face similar problems as program integrators—understanding existing software and making changes that fix bugs or provide enhancements without having a negative impact on the unchanged part of the software. As illustrated by Unravel, slicing is useful in understanding existing software [63]. A new kind of slice, called a *decomposition slice* [28], is useful in making a change to a piece of software without unwanted side effects.

While a slice captures the value of a variable at a particular program point (statement), a decomposition slice captures all computations of a variable and is independent of program location. A decomposition slice is useful to a maintainer when, for example, variable v is determined to have an incorrect value. A differencing tool based on decomposition slicing, called the Surgeon's Assistant [26], partitions a program into three parts (assume the computation of variable v is to be changed):

Independent part: Statements in the decomposition slice taken with respect to v that *are not* in any other decomposition slice.

Dependent part: Statements in the decomposition slice taken with respect to v that *are* in another decomposition slice.

Compliment: Statements that are not independent (i.e., statements in some other decomposition slice, but not v's).

For a maintainer trying to understand the code, only independent and dependent statements (i.e., the decomposition slice taken with respect to v) are of interest. Furthermore, the Surgeon's Assistant only allows modifications of the independent part. This prevents adverse side effects to computations in the compliment. One advantage of this approach is that after making a modification only the independent part need be tested; the complement is guaranteed to be unaffected by the change. The cost of this testing can be significantly lower than testing the entire program. Finally, a program is formed by combining the modified independent part and the unchanged compliment. This can be done in linear time [96]. The merges of [39] are NP-hard. The result is a modified and tested program.

3.7 Reverse Engineering

Reverse engineering concerns the problem of comprehending the current design of a program and the way this design differs from the original design. This involves abstracting out of the source code the design decisions and rationale from the initial development (design recognition) and understanding the algorithms chosen (algorithm recognition).

Program slicing provides a toolset for this type of reabstraction. For example, a program can be displayed as a lattice of slices ordered by the *is-a-slice-of* relation [28, 77, 12]. Comparing the original lattice and the lattice after (years of) maintenance can guide an engineer toward places where reverse engineering energy should be spent. Because slices are not necessarily contiguous blocks of code, they are well suited for identifying differences in algorithms that may span multiple blocks or procedures.

Beck and Eichmann observe that elements "toward the bottom" of this lattice are often *clichés* [12]. For example, in the word count program, the slice that reads the characters from a file is contained in (is-a-slice-of) three other slices (these slices count the number of words, lines, and characters in the input). The common slice is the read-a-file clichè.

Beck and Eichmann also propose the notion of interface slicing for use in reverse engineering. Understanding a program often requires identifying its major abstractions and their interfaces. An interface slice is essentially a forward slice taken with respect to the entry vertices in a collection of

procedures [12]. This projection of a general software module (e.g., a set, list, or window widget) captures the particular behaviors required for a particular use.

An interface slice is computed from an interface dependence graph as a forward graph traversal. The dual of this operation uses a backward graph traversal (i.e., traverses the dependence edges from target to source). Starting from all calls on procedure *P*, this "backward" interface slice includes the public interfaces for those procedures (from other modules) that require *P*.

While interface slicing is useful in reverse engineering, it seems more useful in reshaping the development process. In particular, as Beck and Eichmann observe, a programmer with access to a large repository of software modules often wants only part of the functionality of a module in the repository. Presently, the programmer has two unsatisfactory options: (1) Create a special copy of the module or (2) include unwanted code. The first option requires access to the source code, which may not be possible. It also creates multiple copies of some functions from the module, which complicates later updates. The second option increases the code size and may degrade the performance of the compiler when optimizing the code.

Interface slicing can be used to provide a third alternative that has neither of these deficiencies: The complete module is made available to the interface slicer. A programmer, desiring partial functionality from a module, tells the interface slicer which exported functions are required. The interface slicer then produces the public interface for the required functions without releasing the source for their implementation. Thus a specialized version of the original is made available to the programmer without introducing a new copy or releasing proprietary source code.

3.8 Functional Cohesion

Cohesion is an attribute of a software unit that purports to measure the "relatedness" of the unit. Cohesion has been qualitatively characterized as *coincidental, logical, procedural, communicational, sequential,* and *functional,* with coincidental being the weakest and functional being the strongest [94]. Yourdon and Constantine note that functional cohesion "is an integral part of, and is essential to, the performance of a single function" [94].

To construct a slicing-based measure of functional cohesion, Bieman and Ott [14] define *data slices,* a backward and forward static slice that uses data tokens (variable and constant definitions and references) rather than statements as the unit of decomposition. This definition ensures that any change will impact at least one slice and leads to a *slice abstraction* model

of the procedure under consideration: one can regard the slice as the sequence of variable tokens contained within it.

The tokens that are in every data slice are referred to as *superglue;* tokens that are in more than one data slice are referred to as *glue.* The metrics are based on the ratios of the appearance of glue and superglue tokens in a slice. *Strong functional cohesion* is the ratio of superglue tokens in the slice to the number of tokens in the slice. *Weak functional cohesion* is the ratio of glue tokens in the slice to the number of tokens in the slice.

Another method for measuring cohesion is to measure the *adhesiveness* of the individual tokens. A token that glues five data slices together is more adhesive than a token that glues only two data slices together. Thus, the adhesion of an individual token is the ratio of number of slices in which the token appears to the number of data slices in a procedure.

Bieman and Ott show that these metrics form a well-defined, ordinal measure of the functional cohesion of a program. That is, they show that the orderings imposed match one's intuition. They are unable to show that the metrics are on a ratio scale (that meaningful composition of the metrics exits). The measures are not additive. The study of the relationship of these metrics to product attributes such as reliability and maintainability is ongoing.
